Summary

It is known [1,2] that the use of passive conducting or tuning posts within the input region of a probe-fed circular patch antenna may generally increase the resonant frequency, provide impedance matching or circularly polarized radiation. The input impedance behavior of the antenna based on modal considerations is found useful for the understanding of the performance and for the design of such antennas under various conditions.

Consider a single tuning post placed at $\rho = \rho_1$, $\phi = \phi_0$ within a circular patch antenna fed from the back with a coaxial probe located at $\rho = \rho_0$, $\phi = 0$ degrees, as shown in Fig. 1. It can be shown that in the absence of the post, the dominant (TM$_{11}$) mode E-field at a given $\rho$ and variable $\phi$ may be considered to consist of two degenerate mode fields, referred to as the A- and B-mode, each having a resonant frequency same as that of the antenna (i.e., $f_0$) but the variation of each field in the $\phi$-direction being orthogonal to the other. With a post present, the two modes become distinct having distinct resonant frequency $f_A (= f_0)$ and $f_B$, ($f_B > f_0$), and each mode having a distinct input impedance; under these conditions, the input impedance of the antenna is the sum of the two modal impedances.

The measured input resistance vs frequency for an antenna having one post at $\phi_0 = 135$ degrees and variable $\rho_1$ is shown in Fig. 2 which clearly indicates that with sufficiently large $\rho_1$ the two modes resonate at two distinct frequencies. It is found that $f_A = f_0 = 1415$ MHz in the present case and $f_B > f_0$ and its value significantly depends on $\rho_1$. With $\rho_1$ fixed and $\phi_0$ variable, the input resistance vs. frequency for the same antenna is shown in Fig. 3 which indicates the predominance of A-mode for $\phi_0 = 90$ degrees and that of the B-mode for $\phi_0 = 180$ degrees. These modes can be controlled by proper choice of $\phi_0$, $\rho_1$ and the number of posts to obtain the desired characteristics.
from the antenna. In general, with a single post at \( \phi = \phi_0 \) the modal input resistance may be represented by

\[
R_{\text{in}}^A(\phi_0) = R_0^A \sin^2 \phi_0
\]

\[
R_{\text{in}}^B(\phi_0) = R_0^B \cos^2 \phi_0
\]

where \( R_0^A(\phi_0) \), \( R_0^B(\phi_0) \) are the maximum (resonant) resistance of the A- and B-modes, respectively. In general, it has been found that the input resistance of the antenna depends mainly on \( \phi_0 \), and hence such post(s) can be used for matching; location and number of posts can also be used to increase the resonant frequency of a given circular patch antenna; finally, with proper arrangement of post a single probe-fed antenna can be used to produce circularly polarized radiation. Detailed results including far field patterns will be discussed during the presentation.
